We present a fast, spectrally accurate, automatically differentiable bounce-averaging algorithm implemented in the DESC stellarator optimization suite. Using this algorithm, we can perform efficient optimization of many objectives to improve stellarator performance, such as the  $\epsilon_{\text{eff}}$  proxy for the neoclassical transport coefficient in the low collisionality regime. By employing this differentiable approximation, for the first time, we optimize a finite-beta stellarator to directly reduce neoclassical ripple transport using reverse-mode differentiation. This ensures the cost of differentiation is independent of the number of controllable parameters.

## 1. Introduction

Stellarators, first conceived by Spitzer Jr (1958), represent a distinct approach to magnetic confinement fusion that offers unique advantages over tokamaks. These toroidal devices achieve plasma confinement through external magnetic fields rather than through plasma current, providing greater design flexibility and operational stability. The absence of a continuous toroidal symmetry allows for magnetic field optimization through boundary shaping, which helps minimize the net toroidal current and thereby avoids current-driven plasma disruptions that plague tokamak operation (Helander 2014).

The design of optimal stellarator configurations is a complex optimization problem involving hundreds of degrees of freedom. Traditional optimization approaches have evolved significantly over the past decades. VMEC (Variational Moments Equilibrium Code), developed by Hirshman & Whitson (1983), served as the foundation for stellarator optimization. Building upon VMEC, several frameworks have emerged: STELLOPT (Lazerson *et al.* 2020; Spong *et al.* 1998), which implements a suite of physics-based optimization criteria, ROSE (Drevlak *et al.* 2018), which focuses on coil optimization and engineering constraints, and more recently, SIMSOPT (Landreman *et al.* 2021). In DESC (Dudt *et al.* 2025; Dudt & Kolemen 2020; Panici *et al.* 2023; Conlin *et al.* 2023; Dudt *et al.* 2023), unlike previous optimizers, it is not necessary to re-solve the magnetohydrodynamic (MHD) force balance equation at each optimization step (Conlin *et al.* 2024). Additional objectives that depend on equilibrium force balance can be optimized simultaneously while ensuring force balance.

In general, traditional approaches to stellarator optimization rely on finite difference techniques. Such techniques yield low-order accurate estimates of derivatives that can

† Email address for correspondence: kunalmis@alumni.princeton.edu

‡ Email address for correspondence: ekolemen@princeton.edu

hinder the ability of the optimizer to find good solutions. Furthermore, finite difference techniques require computing the objective function multiple times to estimate the derivative in the direction of each optimizable parameter; this is infeasible when the number of parameters is large. In contrast, automatic differentiation can compute derivatives of the objective with respect to all input parameters in a single computational pass.

We present a fast, automatically differentiable bounce-averaging algorithm that is used to simplify kinetic models such as drift and gyrokinetics that study phenomena at timescales longer than the bounce orbit time. This algorithm has been implemented in the DESC optimization suite. Previous works (Matsuda & Stewart 1986; Nemov *et al.* 1999, 2008; Kernbichler *et al.* 2016; Petrov & Harvey 2016; Lazerson *et al.* 2020; Velasco *et al.* 2020) have used bounce-averaging to accelerate solution of Fokker-Planck equations. However, such works are not compatible with automatically differentiable optimization. Moreover, while they employ respectable numerical techniques, their computation is discretized with lower-order accuracy than in this work or an adaptive quadrature is used, which is expensive to differentiate. This work enables automatically differentiable optimization to improve stellarator performance with exponential accuracy.

In section 2, we present an application of bounce-averaging to compute the neoclassical transport coefficient in the low collisionality regime where the transport coefficients increase with decreasing collision frequency. Section 3 describes the numerical methods to compute the optimization objective. We optimize against neoclassical transport in section 4. In section 5, we conclude this work and explain how it can be extended.

## 2. Neoclassical model of plasma

Our study concerns configurations where magnetic field lines lie on closed, nested toroidal surfaces, known as flux surfaces. We label these surfaces with their enclosed toroidal flux  $\psi$ . Such a divergence-free magnetic field may be written in the Clebsch form (D'haeseleer *et al.* 2012), showing that curves of constant  $(\psi, \alpha)$  trace magnetic field lines.

$$\mathbf{B} = \nabla\psi \times \nabla\alpha \quad (2.1)$$

The dynamics of a magnetized hot plasma differ significantly from that of an unmagnetized fluid. Unlike isotropic hard-sphere collisions that govern the behavior of an uncharged fluid, a plasma behaves differently in directions perpendicular and parallel to the magnetic field lines because of Coulomb collisions. In magnetized plasmas, particles traverse helical trajectories, gyrating around magnetic field lines and drifting across them. The classical transport model assumes a simplistic view of particle collisions and does not adequately incorporate the effects of these drifts. To properly account for these drifts, trapped and passing particles, and the magnetic geometry, we use the neoclassical transport theory.

There are three fundamental length and time scales relevant to magnetized plasmas. The time scales correspond to the particle transit frequency  $v_{\text{th},s}/L_B$ , where  $v_{\text{th},s} = (2T_s/m_s)^{1/2}$  is the thermal speed, the Coulomb collision frequency  $\nu_{ss'} \propto T^{3/2}$ , and the gyration frequency  $\Omega_s = Z_s e |B| / (m_s c)$  where  $s, s'$  are the species of interest,  $Z_s e$  is the charge,  $m_s$  is the mass, and  $c$  is the speed of light. For each time scale, the corresponding length scales are the gradient scale length of the magnetic field  $L_B$ , the mean free path  $\lambda_{\text{mfp}}$ , and the gyroradius  $r_{\text{gyro},s} = v_{\text{th},s}/\Omega_s$ , respectively. In a magnetized plasma,

$$\nu_{ss'} \sim \frac{v_{\text{th},s}}{L_B} \ll \Omega_s \quad (2.2)$$

$$\lambda_{\text{mfp}} \sim L_B \gg r_{\text{gyro},s}. \quad (2.3)$$

Using a random walk estimate, we can calculate the classical heat transport coefficient in the perpendicular direction as  $D_{\perp} \sim \nu_{ss'} r_{\text{gyro},s}^2 \sim T^{5/2}$  (Helander & Sigmar 2005) whereas, using neoclassical theory, we have  $\Delta r \sim r_{\text{gyro},s} |B| / |B|_{\text{poloidal}}$  with  $|B|$  and  $|B|_{\text{poloidal}}$  given by the total and poloidal magnetic field strength, respectively. The transport coefficient is then  $D_{\perp} \sim \nu_{ss'} r_{\text{gyro},s}^2 |B|^2 / |B|_{\text{poloidal}}^2 \sim T^{5/2} |B|^2 / |B|_{\text{poloidal}}^2$ . Note the ratio  $|B| / |B|_{\text{poloidal}}$  strongly depends on the magnetic field geometry and significantly affects the regime of neoclassical transport.

A magnetized plasma can be weakly or strongly collisional. This is defined by the collisionality  $\nu_* = L_B / \lambda_{\text{mfp}}$ . In a strongly collisional plasma, particles undergo frequent collisions without covering a significant distance along a magnetic field line, *i.e.*,  $\nu_* \gg 1$ . Conversely, in a weakly collisional plasma, particles can traverse significant distance before colliding, *i.e.*,  $\nu_* \ll 1$ . Stellarator plasmas in practical applications tend to be weakly collisional.

Based on the stellarator geometry, the weak collisionality regime can be further divided into the banana or plateau regime depending on the reciprocal of the aspect ratio  $\epsilon \sim \iota^{-1} |B|_{\text{poloidal}} / |B|$  where  $\iota$  is the rotational transform (Helander 2014). Most stellarators lie in the regime where the collisionality  $\nu_* \ll \epsilon^{3/2}$ . This categorization is illustrated in figure 1.

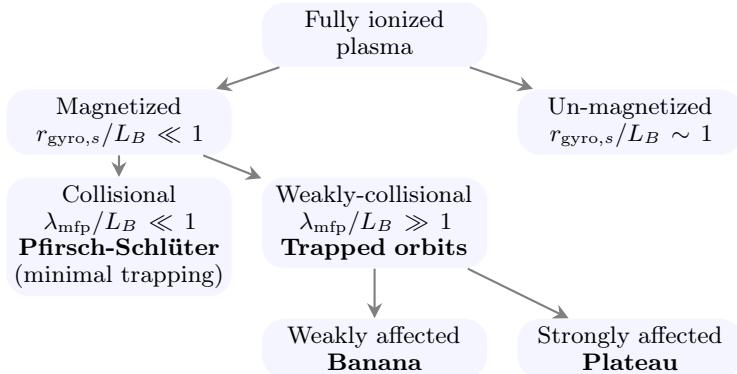

Figure 1: A schematic categorizing neoclassical transport is shown.

The standard neoclassical theory first enabled computation of the neoclassical transport coefficients in the low collisionality regime for a simplified model of the magnetic field. This analysis was later extended to stellarator magnetic fields (Kovrizhnykh 1984; Ochs 2025). The following section outlines this process in one regime of interest to stellarator equilibrium optimization.

### 2.1. Effective ripple

In the low collision limit  $\nu_* \ll \epsilon^{3/2}$ , the neoclassical model studies the plasma distribution  $f$  determined by a simplified Boltzmann equation known as the drift-kinetic equation. For a particle with mass  $m$ , let  $\mathbf{v}_{\parallel}$  and  $\mathbf{v}_{\perp}$  be the velocity parallel and orthogonal, respectively, to the unit vector magnetic field  $\mathbf{b}$ . In the drift-kinetic equation, the velocity space may be parameterized with three independent coordinates: the total energy  $E$ , the magnetic moment  $\mu = m|\mathbf{v}_{\perp}|^2 / (2|B|)$ , and the gyrophase angle. In this treatment, the equation is averaged over the gyrophase angle. We seek a steady-state solution and linearize the distribution of guiding centers  $f = f_0 + f_1$  into a background  $f_0$  that is Maxwellian in velocity and a higher order correction  $f_1$ . Thus, the background is

parameterized in velocity space with  $E$  and the higher order correction with  $(E, \mu)$ . The linearized drift-kinetic equation reduces to the following PDE (Abel *et al.* 2013).

$$\mathcal{C}[f] = \mathbf{v}_{\text{Ds}} \cdot \nabla f_0 + |v_{\parallel}| \mathbf{b} \cdot \nabla f_1 \quad (2.4)$$

$$\mathbf{v}_{\text{Ds}} = \frac{|v_{\parallel}|^2}{\Omega_s} \mathbf{b} \times (\mathbf{b} \cdot \nabla \mathbf{b}) + \frac{|v_{\perp}|^2}{2\Omega_s} \frac{\mathbf{b} \times \nabla |B|}{|B|} + \mathbf{v}_{\text{Baños}} \quad (2.5)$$

The electric field is neglected in this section as we focus on the  $1/\nu$  collisionality regime.

To reduce neoclassical transport, one may minimize the radial particle flux.

$$\Gamma = \int d^3 \mathbf{v} f_1 \mathbf{v}_{\text{Ds}} \cdot \nabla \psi \quad (2.6)$$

Appendix B shows a derivation to extract a dimensionless quantity  $\Gamma_0$  (2.8) for the optimization objective which is proportional to the flux surface average  $\langle \Gamma \rangle$  (B 13).

$$\langle \Gamma \rangle = \Gamma_0 \frac{2^{3/2} \pi c^2}{3^2 e^2 m^{3/2}} \int_0^\infty dE \frac{E^{5/2}}{\nu} \frac{\partial f_0}{\partial \psi} \quad (2.7)$$

$$\Gamma_0 = \left( \int_0^{2\pi} d\alpha \int_{|B|_{\min}}^{|B|_{\max}} \frac{d\varrho}{\varrho^3} \sum_w \frac{I_1^2}{I_2} \right) \left( \int_0^{2\pi} d\alpha \int_{\zeta_1}^{\zeta_2} \frac{d\zeta}{\mathbf{B} \cdot \nabla \zeta} \right)^{-1} \quad (2.8)$$

$$I_1(\psi, \alpha, \varrho, w) = \int_{\zeta_1(w)}^{\zeta_2(w)} \frac{d\zeta}{\mathbf{B} \cdot \nabla \zeta} (1 - |B|/\varrho)^{1/2} (4\varrho/|B| - 1) |\nabla \psi| \kappa_G \quad (2.9)$$

$$I_2(\psi, \alpha, \varrho, w) = \int_{\zeta_1(w)}^{\zeta_2(w)} \frac{d\zeta}{\mathbf{B} \cdot \nabla \zeta} (1 - |B|/\varrho)^{1/2} \quad (2.10)$$

The quantity  $\kappa_G$  is the geodesic curvature of the field line (B 5), and the velocity space coordinate  $\varrho$  is defined as

$$\varrho = E/\mu. \quad (2.11)$$

The number  $w$  indexes the well with boundaries  $\zeta_1(w)$  and  $\zeta_2(w)$  where a bouncing particle is trapped. These boundaries are referred to as bounce points. Only the particles which are trapped within the interval  $[\zeta_1, \zeta_2]$  are considered so that  $\zeta_1 \leq \min_w \zeta_1(w)$  and  $\max_w \zeta_2(w) \leq \zeta_2$ . An illustration is shown in figure 2.

In an axisymmetric configuration, integration along the field line for a single poloidal transit between two global maxima of  $|B|$  is sufficient for convergence of  $\Gamma_0$ . On an irrational magnetic surface, it is sufficient to integrate along a single field line (D'haeseleer *et al.* 2012, section 4.9). On a rational or near-rational surface in a non-axisymmetric configuration, it is necessary to integrate along multiple field lines until the surface is covered sufficiently.

The effective ripple modulation amplitude  $\epsilon_{\text{eff}}$  is related to  $\Gamma_0$  as follows.

$$\epsilon_{\text{eff}}^{3/2} = \frac{\pi}{2^{7/2}} \frac{(B_0 R_0)^2}{\langle |\nabla \psi| \rangle^2} \Gamma_0 \quad (2.12)$$

$B_0$  is a background magnetic field typically chosen to be  $|B|_{\max}$ .  $R_0$  is the average major radius of the stellarator. A reason  $\epsilon_{\text{eff}}$  is preferred to  $\Gamma_0$  as an optimization objective is that the latter vanishes near the magnetic axis, which reduces the ability to distinguish between good and bad configurations. Since  $\epsilon_{\text{eff}}$  is a purely geometry-dependent term, reducing it by varying the stellarator plasma boundary can reduce the radial neoclassical loss of trapped particles.

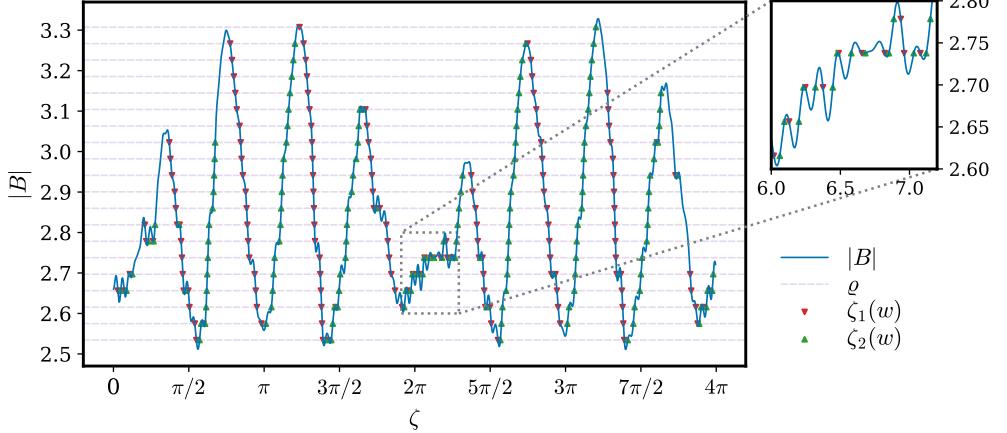

Figure 2: This figure shows bounce points within  $(\zeta_1, \zeta_2) = (0, 4\pi)$  on the field line  $(\psi, \alpha) = (1, 0)$  for a mesh of  $\varrho$  values on a W7-X stellarator. For a given  $\varrho$  marked by a horizontal line,  $|v_{\parallel}| = 0$  at the bounce points marked by triangles. The plasma distribution vanishes in the hypograph of  $|B|$ .

### 3. Algorithm

We briefly describe the fundamental parts of our algorithm. Section 3.1 discusses the bounce integral in more detail. In section 3.2, we describe efficient quadrature used for these integrals. Section 3.3 discusses our inverse method to solve the ideal MHD equation. In sections 3.4, 3.5, and 3.6 we describe our approach to obtain data along field lines.

To motivate the need for an efficient algorithm, let us estimate the cost of bounce-averaging with a blunt approach to the computation. After discretizing to  $N_s$  field lines, where each field line is followed over  $N_w$  magnetic wells for each of  $N_{\varrho}$  pitch angles, there will be  $\mathcal{O}(N_s N_w N_{\varrho})$  bounce integrals. With  $N_q$  quadrature points each, the integrand is evaluated at  $\mathcal{O}(N_s N_w N_{\varrho} N_q) \sim 10^8$  points. Furthermore, the path of integration is unknown *a priori* because the field lines move during optimization. Finding the position of the field lines on a known grid may involve  $N_i$  Newton iterations for each point. With  $N_c$  spectral coefficients used to approximate the map on which that root-finding is done, the cost grows to  $\mathcal{O}(N_c N_i N_s N_w N_{\varrho} N_q)$ . Moreover, the memory required to reverse-mode differentiate the objective grows linearly with the problem size.

#### 3.1. Bounce integral

The bounce integral of  $x$  may be written as a time-weighted integral over the trajectory of the particle along its bounce orbit (Mackenbach *et al.* 2023b, section 2). Since the dynamics parallel to the field lines dominate, the particle trajectory may be approximated to follow field lines by parameterizing time  $t$  as the distance along a field-line following coordinate. Since the magnetic moment is an adiabatic invariant for which the gyro-average of  $d\mu/dt$  is approximately zero, the pitch angle of a bouncing particle stays nearly constant over the timescale to complete bounce orbits when energy is conserved. Labeling the boundaries  $\zeta_1(w)$  and  $\zeta_2(w)$  of magnetic well  $w$  where the parallel velocity vanishes, using the streamline property in curvilinear coordinates

$$|v_{\parallel}|dt = \frac{d\zeta}{\mathbf{b} \cdot \nabla \zeta}, \quad (3.1)$$

and  $|v_{\parallel}|^2 = (2E/m)(1 - |B|/\varrho)$  then allows computing the integral as follows.

$$\bar{x}(\psi, \alpha, \varrho, w) = \frac{m^{1/2}}{(2E)^{1/2}} \int_{\zeta_1(w)}^{\zeta_2(w)} \frac{d\zeta}{\mathbf{b} \cdot \nabla \zeta} (1 - |B|/\varrho)^{-1/2} x \quad (3.2)$$

More generally, integrals between bounce points involve a smooth quantity  $g$  weighted by a non-smooth quantity. The form of the non-smooth quantity is such that its behavior matches  $|v_{\parallel}|^\eta$  near the bounce points.

$$\int_{\zeta_1(w)}^{\zeta_2(w)} d\zeta |v_{\parallel}|^\eta g(\psi, \alpha, \zeta, \varrho) \quad \eta \in \{-1, 1\} \quad (3.3)$$

### 3.2. Quadrature

Gaussian quadrature approximates

$$\int_{-1}^1 dz \zeta g(z) \approx \sum_{i=1}^{N_q} \sigma_i g(z_i) \quad (3.4)$$

for some weight  $\zeta$  positive and continuous in the interior by approximating  $g$  with its Hermite interpolation polynomial and choosing  $\sigma_i, z_i$  to avoid evaluating the derivative ([Süli & Mayers 2003](#)). For singular integrands, a change of variable whose Jacobian vanishes slowly near the singularity can transform the integrand such that it can be approximated well by a low degree polynomial. The transformation should account exactly for the order of the singularity to prevent unnecessary clustering of quadrature points that would increase the condition number of the problem. We define

$$a_1: \begin{cases} \mathbb{N} \times [-1, 1] \rightarrow \mathbb{R} \\ w, z \mapsto (z+1)[\zeta_2(w) - \zeta_1(w)]/2 + \zeta_1(w) \end{cases} \quad (3.5)$$

$$a_2: \begin{cases} [-1, 1] \rightarrow [-1, 1] \\ z \mapsto \sin(\pi z/2) \end{cases} \quad (3.6)$$

and define  $z$  such that  $a_1(w, a_2[z]) = \zeta$  so that

$$\int_{\zeta_1(w)}^{\zeta_2(w)} d\zeta |v_{\parallel}|^\eta g(\zeta) \approx \frac{\zeta_2(w) - \zeta_1(w)}{2} \sum_{i=1}^{N_q} \sigma_i |v_{\parallel}|^\eta g(a_1(w, a_2[z_i])). \quad (3.7)$$

When  $\eta = 1$ , the integrand becomes a smooth and periodic map of  $z$ . Thus, a midpoint scheme yields exponential convergence ([Boyd 2013](#), 88). To be explicit, the quadrature is

$$\sigma_i = \sin\left(i \frac{\pi}{N_q + 1}\right) \frac{\pi}{N_q + 1} \quad \text{and} \quad a_2[z_i] = \cos\left(i \frac{\pi}{N_q + 1}\right). \quad (3.8)$$

When  $\eta = -1$ , the integrand becomes a smooth map of  $z$ , so Gauss-Legendre quadrature may be used. Figures 3, 4, 5, and 6 illustrate the convergence.

When  $\eta = -1$ , the bounce integral (3.2) diverges logarithmically ([Calvo et al. 2017](#), section 4) as  $\varrho$  approaches the value of  $|B|$  at any local maxima within or on the boundary of the integration region. To integrate over the velocity coordinate  $\varrho$ , quadrature which handles logarithmic singularities ([Kapur & Rokhlin 1997](#); [Hao et al. 2014](#)) may be used.

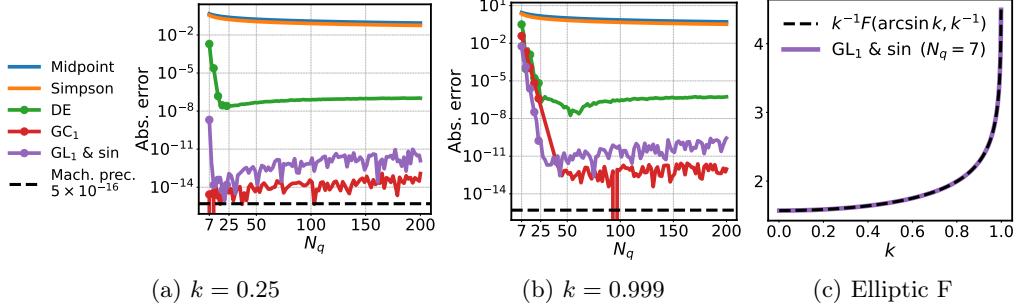

Figure 3: Convergence of quadratures for (3.9). GC<sub>1</sub> and GL<sub>1</sub> show spectral convergence whereas midpoint, Simpson, and double exponential quadratures hit floating point plateaus early.

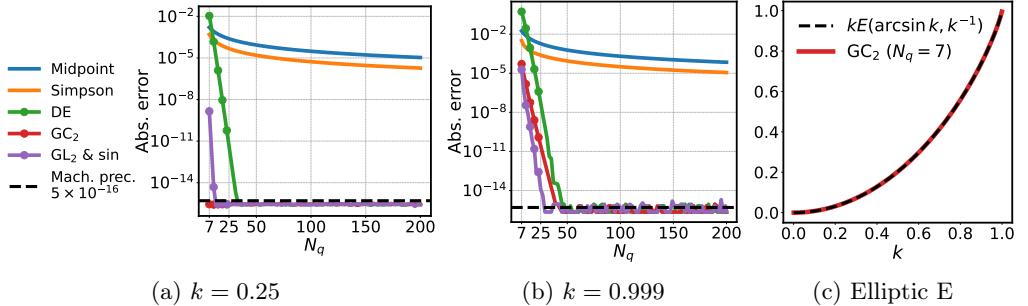

Figure 4: Convergence of quadratures for (3.10). GC<sub>2</sub>, GL<sub>2</sub>, and double exponential quadratures show spectral convergence.

We compare the following quadratures in their ability to compute elliptic integrals (3.9), (3.10), which are similar to bounce integrals in a simple stellarator geometry.

- (i) Open midpoint scheme.
- (ii) Simpson's 1/3 in the interior completed by an open midpoint scheme.
- (iii) Double exponential (DE) tanh – sinh.
- (iv) Implicit Gauss-Chebyshev of the first (GC<sub>1</sub>) or second kind (GC<sub>2</sub>) (3.8). In this context, implicit means the weight function that the Chebyshev basis is orthogonal with respect to is included in the function to integrate.
- (v) Gauss-Legendre (GL<sub>1</sub>) or Gauss-Lobatto-Legendre (GL<sub>2</sub>) each composed with the sin transformation in (3.6). Compared to the Chebyshev quadrature, this quadrature offers more resolution near the boundary and less in the interior.

$$\int_{-\arcsin k}^{\arcsin k} d\zeta (k^2 - \sin^2 \zeta)^{-1/2} \underset{(C11)}{=} 2K(k) \quad (3.9)$$

$$\int_{-\arcsin k}^{\arcsin k} d\zeta (k^2 - \sin^2 \zeta)^{1/2} \underset{(C12)}{=} 2E(k) + 2(k^2 - 1)K(k) \quad (3.10)$$

To further benchmark the quadratures in a magnetic field with ripples, we show two more cases that model particles trapped in the following wells. The quantity labeled by  $f$  on the right is integrated.

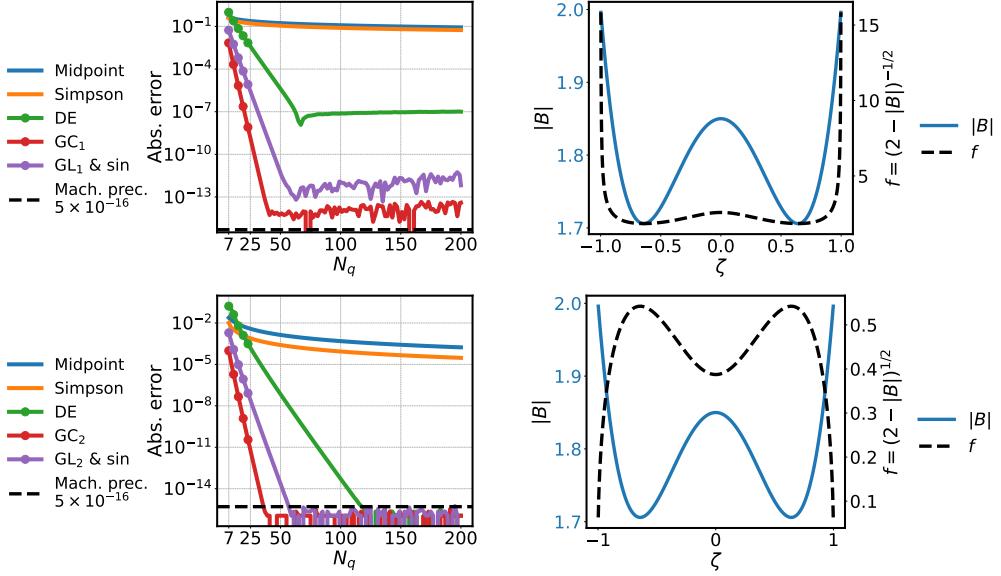

Figure 5: Convergence of quadratures for the well on the right is shown.

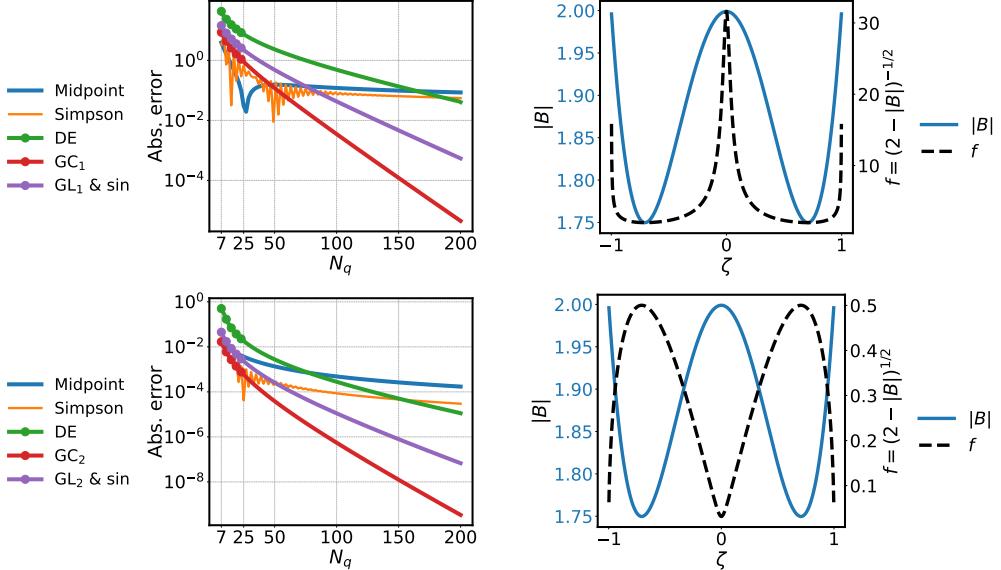

Figure 6: Convergence of quadratures for the well on the right is shown. In the top row, the integrand becomes nearly non-integrable as the parallel velocity nearly vanishes at  $\zeta = 0$ . In either case, splitting the quadrature there recovers fast convergence.

### 3.3. Inverse method

In this section, we briefly discuss how we find stellarator equilibria. At static equilibrium, the ideal MHD equations that approximate the behavior of the plasma reduce to

$$\mathbf{B} \cdot \nabla \mathbf{B} = \nabla(p + |B|^2/2) \quad (3.11)$$

$$\nabla \cdot \mathbf{B} = 0, \quad (3.12)$$

which describes a balance between the plasma pressure  $p$ , magnetic field pressure  $|B|^2$  and the effect of field line curvature  $\mathbf{B} \cdot \nabla \mathbf{B}$ . We solve the ideal MHD equation using an inverse method. The computational domain is a solid torus in curvilinear flux coordinates  $(\rho, \theta, \zeta)$  where  $\rho = (\psi/\psi_{\text{plasma boundary}})^{1/2}$ , and  $(\theta, \zeta)$  are angles on a doubly-periodic surface.  $\Lambda$  and  $\omega$  are to be determined maps that relate the angles  $(\theta, \zeta)$  that parameterize a given plasma boundary to the Clebsch angle.

$$\alpha = \theta + \Lambda - \iota(\zeta + \omega) \quad (3.13)$$

Fourier-Zernike series parameterized in flux coordinates  $(\rho, \theta, \zeta)$  are chosen to approximate  $\Lambda$ ,  $\omega$ , and the map to a cylindrical coordinate system  $(R, \phi, Z)$  in the lab frame.

$$R(\rho, \theta, \zeta) \hat{\mathbf{R}}(\phi) + Z(\rho, \theta, \zeta) \hat{\mathbf{Z}} \quad (3.14)$$

It can be shown from (2.1) that  $\nabla \theta \times \nabla \zeta \neq \mathbf{0}$  implies (3.15) and (3.16).

$$\mathbf{B} \cdot \nabla \theta = -[\nabla \psi \cdot (\nabla \theta \times \nabla \zeta)] \left( \frac{\partial \alpha}{\partial \zeta} \right)_{\psi, \theta} \quad (3.15)$$

$$\mathbf{B} \cdot \nabla \zeta = +[\nabla \psi \cdot (\nabla \theta \times \nabla \zeta)] \left( \frac{\partial \alpha}{\partial \theta} \right)_{\psi, \zeta} \quad (3.16)$$

Thus, we find equilibria by searching for a combination  $(R, Z, \Lambda, \omega)$  to reduce the force balance error (3.11) at a set of collocation points using pseudo-spectral methods, subject to constraints on the pressure profile and the rotational transform or toroidal current profile. This boundary value problem is then solved as a minimization problem using a trust-region method. In an optimization constrained by force balance, varying  $(R, Z, \Lambda, \omega)$  changes the magnetic field and (3.14) such that (3.13) remains valid.

Two advantages of this inverse approach for optimization with bounce-averaged objectives are stated below.

- (i) The variables  $(\theta, \zeta)$  on the boundary surface may be constructed so that maps parameterized in these coordinates are spectrally condensed (Hirshman & Breslau 1998; Hindenlang *et al.* 2025). Consequently, maps parameterized in  $(\rho, \theta, \zeta)$  in the plasma volume tend to have spectral expansions that converge more rapidly.
- (ii) Force balance and other geometric objectives are best computed on a particular grid in  $(\rho, \theta, \zeta)$  which is fixed throughout optimization. This ensures the spectral basis for  $(R, Z, \Lambda, \omega)$  can be precomputed, avoiding “off-grid” interpolation of a three-dimensional basis that bottlenecks pseudo-spectral codes (Boyd 2013, section 10.7). Furthermore, if the coordinate system varied throughout the optimization, then so does the optimal grid for interpolation and quadrature. To preserve spectral accuracy, a pseudo-spectral code must first find this optimal grid and compute the basis there. This “moving-grid” interpolation is doubly expensive in optimization because the mentioned tasks must also be differentiated, which consumes significant memory.

These qualities enable faster generation of magnetic field data, which we discuss in the following section.

### 3.4. Fast interpolation

In this section, we outline our method for fast interpolation.

The Zernike basis concentrates the frequency transform of smooth maps on discs at lower frequencies than geometry-agnostic tensor-product bases. Boyd & Yu show the required number of spectral coefficients is typically half that of Fourier-Chebyshev (Boyd & Yu 2011). This ensures an optimization that varies a finite number of coefficients in the Fourier-Zernike series for  $(R, Z, \Lambda, \omega)$  at a time has more freedom compared to expansions in other bases. However, the Zernike basis is expensive to evaluate.

Our algorithm computes the Fourier-Zernike basis once prior to optimization on a uniform  $K_\theta \times K_\zeta$  grid in  $(\theta, N_{\text{FP}}\zeta) \in [0, 2\pi]^2$  on each surface. Any smooth, periodic map  $g$  required by the objective is computed from  $(R, Z, \Lambda, \omega)$  on this grid and interpolated with a fast Fourier transform (FFT). The resulting Fourier series are evaluated using type 2 non-uniform FFTs with linearithmic cost in  $K_\theta K_\zeta$  and linear cost in the number of points to evaluate (Barnett et al. 2019; Barnett 2021; hsuan Shih et al. 2021).

$$g_{k_\theta k_\zeta} = \frac{c_{k_\theta}}{4\pi^2} \iint_{[0, 2\pi)^2} d\theta d(N_{\text{FP}}\zeta) g(\theta, N_{\text{FP}}\zeta) e^{-ik_\theta\theta} e^{-ik_\zeta N_{\text{FP}}\zeta} \quad (3.17)$$

$$g(\alpha, \zeta) = \sum_{k_\theta=0}^{\lfloor K_\theta/2 \rfloor} \sum_{k_\zeta=-\lfloor K_\zeta/2 \rfloor}^{\lceil K_\zeta/2 \rceil - 1} \text{Real}\left(g_{k_\theta k_\zeta} e^{ik_\theta\theta(\alpha, \zeta)} e^{ik_\zeta N_{\text{FP}}\zeta}\right) \quad (3.18)$$

$$c_{k_\theta} = 1 \text{ if } k_\theta \in \{0, K_\theta/2\} \text{ else } 2$$

### 3.5. Map to the mesh of field lines

Evaluating maps along field lines requires finding the position of the field lines on some grid. To identify the coordinate  $\theta$  at a given point  $(\alpha, \zeta)$  one may solve equation (3.13). To avoid repeating that inversion everywhere our objective demands, we compute the spectral projection  $\{a_{xy}\}$  of the map  $\alpha, \zeta \mapsto \theta - \alpha$  onto a tensor-product basis  $\{b_{xy}\}$  that is orthogonal with respect to some weight  $\varsigma$ .

$$a_{xy} \sim \iint d\alpha d\zeta (\theta - \alpha) \varsigma b_{xy}^*(\alpha, \zeta) \quad (3.19)$$

The Fourier-Chebyshev basis defined on the field period  $(\alpha, N_{\text{FP}}\zeta) \in [0, 2\pi]^2$  is chosen for reasons discussed in (Mason & Handscomb 2002, section 5.5, 5.6, 6.3.4) and (Boyd 2013, section 4.5).

$$b_{xy}(\alpha, \zeta) = e^{ix\alpha} \cos(y \arccos[N_{\text{FP}}\zeta/\pi - 1]) \quad (3.20)$$

On each flux surface, equation (3.13) is solved on a tensor-product grid of size  $X \times Y$  on the Fourier nodes across field lines and the Chebyshev nodes along field lines using Newton iteration with a backtracking line search. The series (3.19) is computed by interpolating  $\theta - \alpha$  on that grid with a discrete cosine transform along field lines, followed by an FFT across field lines. The convergence of the series is illustrated in figure 7.

To extend the map beyond a single field period, we use

$$\theta \equiv \alpha_{\text{mod}} + \sum_{x=0}^{\lfloor X/2 \rfloor} \sum_{y=0}^{Y-1} \text{Real}(a_{xy} b_{xy}(\alpha_{\text{mod}}, \zeta_{\text{mod}})) \pmod{2\pi} \quad (3.21)$$

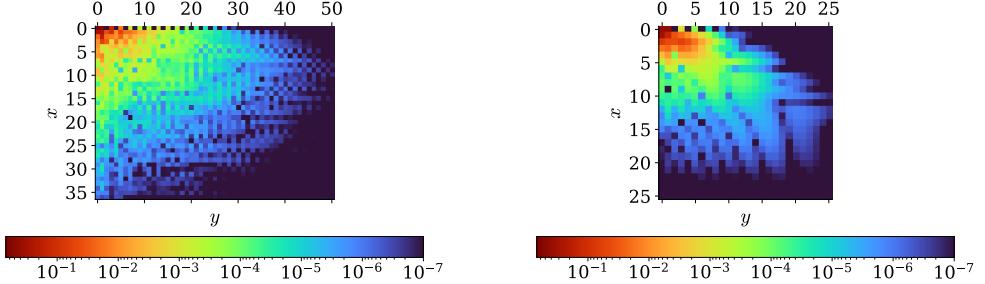

$$\alpha_{\text{mod}} = \alpha_{\text{shift}} \pmod{2\pi}$$

$$\alpha_{\text{shift}} = \alpha + \iota \lfloor N_{\text{FP}}\zeta/(2\pi) \rfloor 2\pi/N_{\text{FP}}$$

$$\zeta_{\text{mod}} = \zeta \pmod{2\pi/N_{\text{FP}}}.$$

The equivalence (3.21) is due to  $\alpha + \iota\zeta = \alpha_{\text{shift}} + \iota\zeta_{\text{mod}}$  and uniqueness of solutions to (3.13). Figure 8 shows an illustration. The construction and evaluation of this series is accelerated with partial summation (Boyd 2013, section 10).

This approach avoids issues that result from changing the basis for  $(R, Z, \Lambda, \omega)$  at each optimization step (appendix D).

(a)  $|a_{xy}|$  on the plasma boundary of an NCSX stellarator with  $N_{\text{FP}} = 3$ . (b)  $|a_{xy}|$  on the plasma boundary of a Heliotron stellarator with  $N_{\text{FP}} = 19$ .

Figure 7: These figures show the convergence of the spectral projection of  $\alpha, \zeta \mapsto \theta - \alpha$  onto the Fourier-Chebyshev basis (3.21). Equation (3.13) was solved to error  $\leq 10^{-7}$ . Note that if  $\omega \rightarrow \Lambda/\iota$  then  $\theta - \alpha \rightarrow \iota\zeta$ , so the spectral width reduces to one parameter. Thus, if the optimizer is motivated to match higher frequency spectral coefficients of  $\omega$  with  $\Lambda/\iota$ , then field lines can be tracked at lower resolution.

### 3.6. Jacobian of the map to the mesh of field lines

In this section, we explain how we accelerate the iterative solve discussed in the previous section throughout optimization. To bypass differentiating the iterative solve, we write the tangent and adjoint methods directly (Sapienza *et al.* 2025, section 3.3.3, 3.9.2). For this task, we leverage the implicit function theorem to differentiate solutions  $\theta^*$  to (3.13) with respect to the optimizable parameters, denoted here with  $\mathbf{x}_{\text{opt}}$ . Define

$$f: \mathbf{x}_{\text{opt}}, \theta \mapsto \theta - \iota\omega - \Lambda - \alpha - \iota\zeta.$$

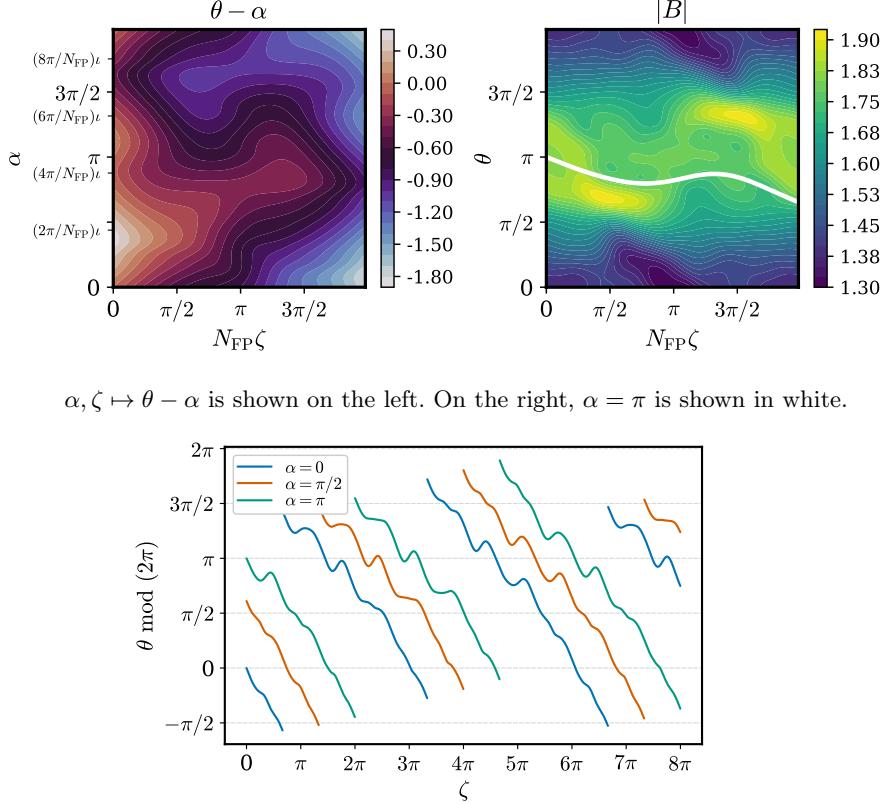

Let  $(\mathbf{x}_{\text{opt}}^*, \theta^*)$  satisfy  $f(\mathbf{x}_{\text{opt}}^*, \theta^*) = 0$ .

$$\frac{\partial f}{\partial \theta}(\mathbf{x}_{\text{opt}}^*, \theta^*) = 1 - \frac{\partial(\iota\omega - \Lambda)}{\partial \theta}(\mathbf{x}_{\text{opt}}^*, \theta^*) \underset{(3.13)}{=} \left( \frac{\partial \alpha}{\partial \theta} \right)_{\psi, \zeta}(\mathbf{x}_{\text{opt}}^*, \theta^*) \quad (3.22)$$

In the  $(\psi, \alpha, \zeta)$  covariant basis, the only nonzero component of the non-vanishing magnetic field is (3.16), so the derivative (3.22) is invertible. By the implicit function theorem,  $\theta^*$  is a continuously differentiable map of  $\mathbf{x}_{\text{opt}}$  and  $f(\mathbf{x}_{\text{opt}}, \theta^*(\mathbf{x}_{\text{opt}})) = 0$  near  $\mathbf{x}_{\text{opt}}^*$ . Moreover,

$$\frac{\partial \theta^*}{\partial \mathbf{x}_{\text{opt}}}(\mathbf{x}_{\text{opt}}) = - \left[ \frac{\partial f}{\partial \theta}(\mathbf{x}_{\text{opt}}, \theta^*(\mathbf{x}_{\text{opt}})) \right]^{-1} \frac{\partial f}{\partial \mathbf{x}_{\text{opt}}}(\mathbf{x}_{\text{opt}}, \theta^*(\mathbf{x}_{\text{opt}})). \quad (3.23)$$

Thus, we differentiate directly through the solution  $\theta^*$ . Likewise, after updating  $\mathbf{x}_{\text{opt}}$ , we use (3.23) to warm start the next Newton iteration at an initial value that is correct to first order.

$\alpha, \zeta \mapsto \theta - \alpha$  is shown on the left. On the right,  $\alpha = \pi$  is shown in white.

Figure 8:  $\theta$  on the plasma boundary of an NCSX stellarator with  $N_{\text{FP}} = 3$ .

#### 4. Optimization for reduced neoclassical transport

We present an optimization starting from a finite-beta helically omnigenous (OH) equilibrium. Finite-beta refers to the nonzero ratio of plasma pressure and magnetic pressure. We target flux surfaces near the boundary to reduce the effective ripple while maintaining reasonable elongation and curvature. With weights,  $w_A, w_C, w_E, w_O, w_R$ , the objective (4.1) is minimized while ensuring ideal MHD force balance (3.11) is maintained.

$$w_A f_{\text{aspect}}^2 + w_C f_{\text{curv}}^2 + w_E f_{\text{elongation}}^2 + w_O f_{\text{omni}}^2 + w_R f_{\text{ripple}}^2 \quad (4.1)$$

The initial equilibrium along with the definitions of the curvature and elongation objectives are provided in Gaur *et al.* (2025a); Gaur (2024). The results are presented in figure 9. The optimization took less than two hours with a GPU (NVIDIA Corporation 2020).

The omnigenicity objective is based on the work of Dudit *et al.* (2024), where it was shown that optimizing for omnigenicity can in turn reduce the effective ripple. Directly optimizing to reduce the effective ripple instead has the advantage that the optimizer is not biased toward a user-specified omnigenous field. For example in Gaur *et al.* (2025b), we used this property to optimize for an umbilic boundary while maintaining a low effective ripple without biasing the optimizer toward an omnigenous field with a specific helicity.

It should be noted that the assumptions used to derive the effective ripple increase in validity as the magnetic field becomes more omnigenous. For example, the bounce-averaged approach presented here assumes the radial orbit width is small compared to the magnetic field gradient scale length  $\Delta r \ll L_B$ . When finite orbit width effects

become dominant, particles may traverse “potato” orbits requiring a more global treatment ([Satake \*et al.\* 2002](#)). Hence, there is utility in optimization that uses both objectives, either simultaneously or in succession.

## 5. Conclusions

In this work, we optimized a finite-beta configuration to directly reduce neoclassical transport using reverse-mode differentiation. More generally, we upgraded the DESC stellarator optimization suite for fast, accurate, automatically differentiable bounce-averaging. We discussed how we perform moving-grid interpolation without sacrificing spectral accuracy. This accuracy ensures that changes in the objective due to small changes in controllable parameters reflect genuine improvement or degradation rather than noise due to error. Therefore, optimization is more likely to be successful.

Our algorithm enables optimization for many objectives to improve stellarator performance. These include maximization of the second adiabatic invariant ([Helander 2014](#), section 3.7), ([Rodríguez \*et al.\* 2024](#)), energetic particle confinement ([Nemov \*et al.\* 2008; Velasco \*et al.\* 2021](#)), and proxies for gyrokinetic turbulence such as the available energy ([Mackenbach \*et al.\* 2022, 2023a](#)). We have currently added all but the latter as objectives to DESC. Some of these objectives have previously had limited use in optimization due to expensive computational requirements or difficulty finding desirable configurations. Further demonstration of optimization with them remains as future work.

## Acknowledgments

This work is funded through the SciDAC program by the US Department of Energy, Office of Fusion Energy Science, and Office of Advanced Scientific Computing Research under contract numbers DE-AC02-09CH11466, DE-SC0022005, and Field Work Proposal No. 1019. This work was also funded by the Peter B. Lewis Fund for Student Innovation in Energy and the Environment. This research used the resources of the Della computing cluster at Princeton University.

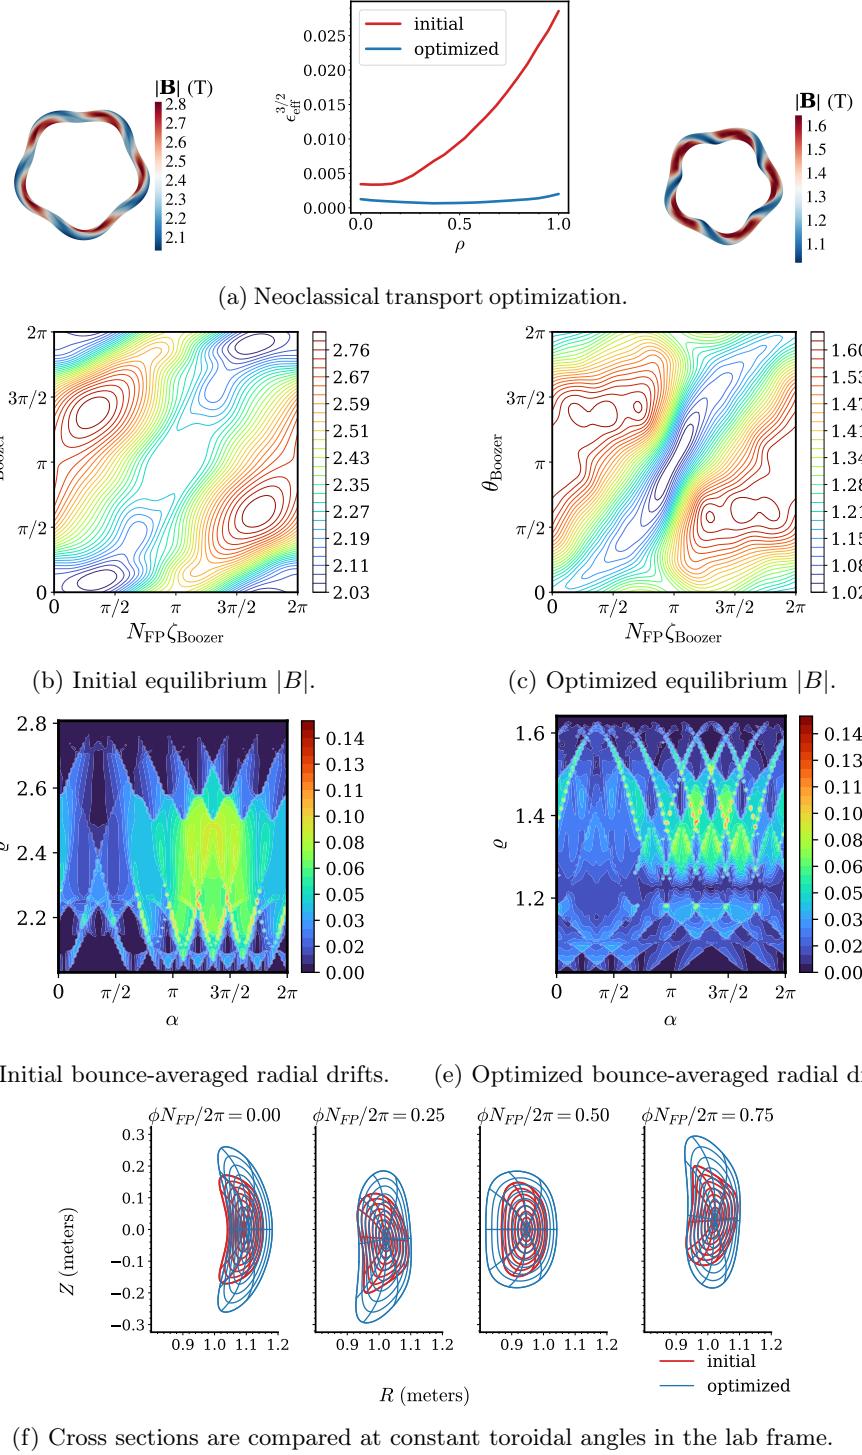

Figure 9: An OH transport optimization. Figures 9b, 9c are shown in Boozer coordinates (D'haeseleer *et al.* 2012). Figures 9d, 9e show bounce-averaged radial drifts, summed in magnitude over  $\zeta \in (0, 2\pi)$ . The size of the region with large drifts appears reduced.

## Appendix A. Open source code

The implementation and supplementary information describing how correctness of automatic differentiation is enforced may be found in the `DESC` repository ([Dudt et al. 2025](#)). The implementation uses accelerated linear algebra `XLA` and Google’s `JAX` library ([Bradbury et al. 2018](#)). JIT compilation in `JAX` compiles the code at the start of an optimization. Optimization may be accelerated on CPUs, GPUs, and TPUs.

## Appendix B. Effective ripple

We explain a short derivation of  $\epsilon_{\text{eff}}$ , similar to the one used in [Nemov et al. \(1999\)](#).

To obtain an explicit expression for  $f_1$  from (2.4), we will bounce-integrate the drift-kinetic equation. Applying this operator to the drift-kinetic equation discretizes the spatial coordinate  $\zeta$  to a set of integral equations labeled by the magnetic well index  $w$ .

The collision operator in (2.4) is chosen to capture pitch angle scattering.

$$\mathcal{C}[f] = \nu m \frac{|v_{\parallel}|}{|B|} \frac{\partial}{\partial \mu} \left( \mu |v_{\parallel}| \frac{\partial f}{\partial \mu} \right) \quad (\text{B } 1)$$

These derivatives are at fixed position and energy. The collision frequency  $\nu$  depends only on the energy of the particle. The velocity ratio is  $|v_{\parallel}|/|v| = (1 - |B|/\varrho)^{1/2}$ . The nullspace of this collision operator contains velocity-isotropic distributions, so  $\mathcal{C}[f_0 + f_1] = \mathcal{C}[f_1]$ . In this form, (2.4) is the linearized Lorentz-gas Fokker-Planck equation ([Goldston & Rutherford 1995](#), section 13).

In weakly collisional plasmas, the collision frequency is small compared to the particle bounce frequency. Consequently, fluctuations due to collisions homogenize along field lines rapidly, implying that the spatial variation in the plasma distribution along field lines in any particular magnetic well is small. Therefore, we approximate  $f_0$  and  $f_1$  to be spatially uniform along field lines in any particular magnetic well.

$$\nabla f = \left( \frac{\partial f}{\partial \psi} \right)_{\alpha, \zeta, E, \mu} \nabla \psi + \left( \frac{\partial f}{\partial \alpha} \right)_{\psi, \zeta, E, \mu} \nabla \alpha + \left( \frac{\partial f}{\partial \zeta} \right)_{\psi, \alpha, E, \mu} \nabla \zeta \quad (\text{B } 2)$$

$$|\nabla f| \gg |(\partial f / \partial \zeta) \nabla \zeta| \quad (\text{B } 3)$$

Nested flux surfaces (2.1) then imply the parallel drift  $\mathbf{v}_{\text{Baños}}$  and the parallel spatial derivative of  $f_1$  will be negligible in the bounce-integrated drift-kinetic equation.

$$\begin{aligned} \overline{\mathcal{C}[f_1]} &= \nu m \frac{\partial}{\partial \mu} \mu \int \frac{d\zeta}{\mathbf{b} \cdot \nabla \zeta} \frac{|v_{\parallel}|}{|B|} \frac{\partial f_1}{\partial \mu} \\ &= \nu m \frac{\partial}{\partial \mu} \mu \frac{\partial f_1}{\partial \mu} \frac{|v_{\parallel}|^2 / |B|}{|v_{\parallel}|^2 / |B|} \\ &= \frac{\partial f_0}{\partial \psi} \overline{\mathbf{v}_{\text{Ds}} \cdot \nabla \psi} \end{aligned} \quad (\text{B } 4)$$

To write the last relation (B4), we assume there are sufficiently many passing particles so that  $f_0$  is independent of  $\alpha$ .<sup>†</sup> We proceed to invert the collision operator. First label the geodesic curvature of the field line.

$$\kappa_G = [\mathbf{b} \times (\mathbf{b} \cdot \nabla \mathbf{b})] \cdot \frac{\nabla \psi}{|\nabla \psi|} = \frac{\mathbf{b} \times \nabla |B|}{|B|} \cdot \frac{\nabla \psi}{|\nabla \psi|} \quad (\text{B } 5)$$

<sup>†</sup> The claim  $|\overline{(\partial f_0 / \partial \alpha) \mathbf{v}_{\text{Ds}} \cdot \nabla \alpha}| \ll |\overline{\mathbf{v}_{\text{Ds}} \cdot \nabla f_0}|$  requires care because  $|\nabla \alpha|$  grows unbounded when the magnetic shear is nonzero. If the distribution has variation across field lines, we assume it is captured by the higher order correction  $f_1$ .

The second equality is a consequence of ideal MHD force balance (3.11). Now the primitive with respect to  $\mu$  of the bounce-integrated radial drift velocity is identified as follows.

$$\frac{\partial}{\partial \mu} \overline{|v_{\parallel}| \beta} = \overline{\mathbf{v}_{Ds} \cdot \nabla \psi} \quad (\text{B } 6)$$

$$\frac{\partial \beta}{\partial \mu} = \frac{\mathbf{v}_{Ds} \cdot \nabla \psi}{|v_{\parallel}|} = (|v|^2 |v_{\parallel}|^{-1} + |v_{\parallel}|) \frac{|\nabla \psi| \kappa_G}{2 \Omega_s} \quad (\text{B } 7)$$

$$\beta = -(3|v|^2 |v_{\parallel}| + |v_{\parallel}|^3) \frac{m |\nabla \psi| \kappa_G}{6 \Omega_s |B|} \quad (\text{B } 8)$$

Inverting the  $\mu$  derivative in equation (B 4) completes the inversion of the collision operator.

$$\begin{aligned} \nu m \frac{\partial}{\partial \mu} \left( \mu \frac{\partial f_1}{\partial \mu} \overline{|v_{\parallel}|^2 / |B|} \right) &= \frac{\partial}{\partial \mu} \left( \frac{\partial f_0}{\partial \psi} \overline{|v_{\parallel}| \beta} \right) \\ \frac{\partial f_1}{\partial \mu} &= \frac{\partial f_0}{\partial \psi} \frac{\overline{|v_{\parallel}| \beta}}{\nu m \mu \overline{|v_{\parallel}|^2 / |B|}} \end{aligned} \quad (\text{B } 9)$$

To compute (2.6) we will use the  $(E, \mu)$  parameterization of velocity space.

$$\int d^3 v = \frac{2\pi}{m^2} |B| \int_0^\infty dE \int_0^{E/|B|} \frac{d\mu}{|v_{\parallel}|} \quad (\text{B } 10)$$

$$= \frac{2^{1/2}\pi}{m^{3/2}} |B| \int_0^\infty dE E^{1/2} \int_\infty^{|B|} \frac{d\rho}{\rho^2 (1 - |B|/\rho)^{1/2}} \quad (\text{B } 11)$$

The plasma distribution vanishes where  $\mu \geq E/|B|$ , so the integration region was truncated. Using (B 10), applying integration by parts in the  $\mu$  coordinate, and enforcing the boundary condition  $\lim_{\mu \rightarrow 0} f_1 = 0$  at fixed energy, the radial particle flux (2.6) can be written in terms of known quantities as follows.

$$\Gamma = - \int d^3 v |v_{\parallel}| \beta \frac{\partial f_1}{\partial \mu} \quad (\text{B } 12)$$

To make optimization efficient, the flux surface average of the radial particle flux is of interest to minimize. This is the average on an infinitesimal volume covering the surface.

$$\langle \Gamma \rangle = \left( \int \frac{ds}{|\nabla \psi|} F \right) \left( \int \frac{ds}{|\nabla \psi|} \right)^{-1} \quad (\text{B } 13)$$

Here  $ds$  is the differential surface area Jacobian. As equation (B 12) enables computing the radial particle flux through bounce integrals along the magnetic field line (B 9), it is more tractable to also compute the flux surface average along the field line.

$$\langle \Gamma \rangle = \left( \int_0^{2\pi} d\alpha \int_{\mathbb{R}} \frac{d\zeta}{\mathbf{B} \cdot \nabla \zeta} F \right) \left( \int_0^{2\pi} d\alpha \int_{\mathbb{R}} \frac{d\zeta}{\mathbf{B} \cdot \nabla \zeta} \right)^{-1} \quad (\text{B } 14)$$

We proceed to extract a dimensionless quantity  $\Gamma_0$  for the optimization objective. First we use (B 11) and (B 14) to remove the spatial dependence in the boundary of the velocity

integral.

$$\begin{aligned} \langle I \rangle &= \frac{2\pi}{m^2} \left( \int_0^{2\pi} d\alpha \int_0^\infty dE E \int_{|B|}^\infty \frac{d\varrho}{\varrho^2} \int_{\mathbb{R}} \frac{d\zeta}{\mathbf{b} \cdot \nabla \zeta} \beta \frac{\partial f_1}{\partial \mu} \right) \left( \int_0^{2\pi} d\alpha \int_{\mathbb{R}} \frac{d\zeta}{\mathbf{B} \cdot \nabla \zeta} \right)^{-1} \\ &= \frac{2\pi}{m^2} \left( \int_0^{2\pi} d\alpha \int_0^\infty dE E \int_{|B|_{\min}}^{|B|_{\max}} \frac{d\varrho}{\varrho^2} \sum_w \overline{|v_\parallel|} \beta \frac{\partial f_1}{\partial \mu} \right) \left( \int_0^{2\pi} d\alpha \int_{\mathbb{R}} \frac{d\zeta}{\mathbf{B} \cdot \nabla \zeta} \right)^{-1} \end{aligned} \quad (\text{B } 15)$$

Here  $|B|_{\min}$  and  $|B|_{\max}$  are the min and max values on the flux surface. The integral was truncated at  $|B|_{\max}$  as  $f_1 = 0$  for passing particles. Now changing coordinates in (B 8)

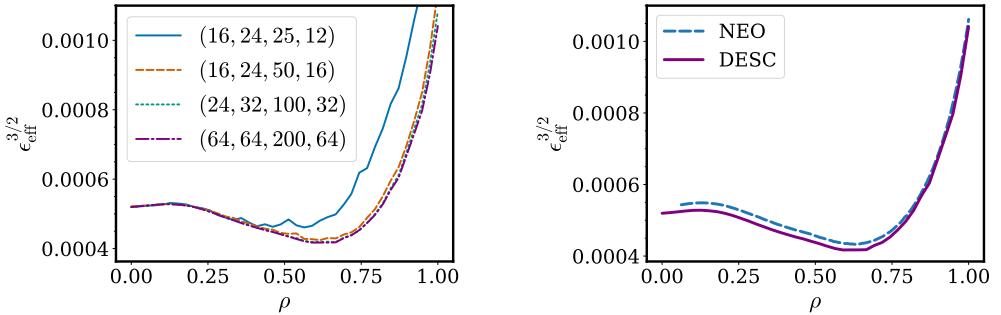

$$\beta = -\frac{(2mE^3)^{1/2}c}{3\varrho e|B|}(1-|B|/\varrho)^{1/2}(4\varrho/|B|-1)|\nabla\psi|\kappa_G \quad (\text{B } 16)$$

and using the new partition for the velocity integral (B 15), the expression (B 14) may be approximated using a sum over all wells in the interval  $[\zeta_1, \zeta_2]$  (2.7).

### B.1. Resolution scan for the neoclassical transport coefficient

Figure 10a presents a resolution scan for  $\epsilon_{\text{eff}}$ . Figure 10b compares the result to the NEO code (Nemov *et al.* 1999), which uses a finite difference technique and requires transforming to Boozer coordinates. For the singular integrals, NEO uses a Runge-Kutta scheme equivalent to the Simpson method.

We mention some performance benchmarking below. Computing  $\epsilon_{\text{eff}}$  and its derivative with respect to all parameters, on ten flux surfaces, following each field line for 75 field periods, with resolution  $(K_\theta, K_\zeta, X, Y, N_\varrho, N_q) = (32, 32, 32, 32, 100, 32)$  was profiled to take less than one and ten seconds, respectively, with a CPU (Intel Corporation 2019). These computations are at least an order of magnitude faster with a GPU.

(a) Five field lines are followed for 100 field periods. The legend shows the resolution  $(X, Y, N_\varrho, N_q)$ .  $K_\theta = K_\zeta = 33$ .

(b) NEO-DESC comparison.

Figure 10: Resolution scan for  $\epsilon_{\text{eff}}$  on the W7-X equilibrium in the DESC repository.

## Appendix C. Bounce-averaged drifts in a shifted-circle model

In a shifted-circle model for plasma equilibrium, we can obtain analytical expressions for bounce-averaged drifts. We further verify our algorithm with this model in figure 11.

In this model, the magnetic field can be written

$$\mathbf{B} = \nabla\alpha \times \nabla\chi = F\nabla\phi + \frac{d\chi}{d\rho} \frac{\rho}{R_0} \nabla\vartheta \quad (\text{C } 1)$$

where  $\alpha = \phi - \iota^{-1}\vartheta$ ,  $\chi$  is the poloidal flux,  $F$  is the enclosed poloidal current,  $R_0$  is the average major radius, and  $\rho$  is a radial coordinate. To lowest order, the Grad-Shafranov equation has the constant solution  $F = F_0$ . To the next order, the pressure gradient is

$$dp/d\rho = -F_0 R^{-2} (dF/d\rho). \quad (\text{C } 2)$$

To first order, the poloidal magnetic field can be ignored so that the field satisfies  $|B| = B_0(1 - \epsilon \cos \vartheta)$  and  $\mathbf{b} \cdot \nabla\vartheta = G_0(1 - \epsilon \cos \vartheta)$  where  $\epsilon \ll 1$  is the reciprocal of the aspect ratio.  $B_0$  and  $G_0$  are constants. In this model, the global shear  $\hat{s}$ , normalized pressure gradient, and integrated local shear are

$$\hat{s} = -\rho\iota^{-1}(d\iota/d\rho) \quad (\text{C } 3)$$

$$\alpha_{\text{MHD}} = -2^{-1}\iota^{-2}(dp/d\rho) \quad (\text{C } 4)$$

$$\text{gds21} = (d\chi/d\rho)(d\iota^{-1}/d\rho)\nabla\chi \cdot \nabla\alpha = -\hat{s}(\hat{s}\vartheta - |B|^{-4}\alpha_{\text{MHD}} \sin \vartheta) + \mathcal{O}(\epsilon). \quad (\text{C } 5)$$

The binormal, geometric part of the  $\nabla|B|$  drift is

$$(\nabla|B|)_{\text{drift}} = |B|^{-3}(\mathbf{B} \times \nabla|B|) \cdot \nabla\alpha = f_2(-\hat{s} + \cos \vartheta - \hat{s}^{-1}\text{gds21} \sin \vartheta). \quad (\text{C } 6)$$

The binormal, geometric part of the curvature drift is

$$\begin{aligned} \text{cvdrift} &= |B|^{-3}[\mathbf{B} \times \nabla(p + |B|^2/2)] \cdot \nabla\alpha \\ &= (\nabla|B|)_{\text{drift}} + f_3|B|^{-3}(dp/d\rho) \\ &= f_2(-\hat{s} + \cos \vartheta + \hat{s}\vartheta \sin \vartheta - B_0^{-4}\alpha_{\text{MHD}} \sin^2 \vartheta) + f_3B_0^{-2}\alpha_{\text{MHD}} + \mathcal{O}(\epsilon). \end{aligned} \quad (\text{C } 7)$$

The scalars  $f_2$  and  $f_3$  contain some constants. The bounce-averaged drift is

$$\langle v_D \rangle = \left( \int_{\vartheta_1}^{\vartheta_2} \frac{d\vartheta}{\mathbf{b} \cdot \nabla\vartheta} |v_{\parallel}|^{-1} \right)^{-1} \int_{\vartheta_1}^{\vartheta_2} \frac{d\vartheta}{\mathbf{b} \cdot \nabla\vartheta} \left[ |v_{\parallel}| \text{cvdrift} + \frac{|v_{\perp}|^2}{2|v_{\parallel}|} (\nabla|B|)_{\text{drift}} \right]. \quad (\text{C } 8)$$

As used in Connor *et al.* (1983) and shown by Hegna (2015), in the limit of a large aspect ratio shifted-circle model, the parallel speed of a particle with a fixed energy is  $|v_{\parallel}| = (2E/m)^{1/2}(2\epsilon\lambda B_0)^{1/2}(k^2 - \sin^2(\vartheta/2))^{1/2}$  where

$$k^2 = 2^{-1}[(1 - \lambda B_0)(\epsilon\lambda B_0)^{-1} + 1] \quad (\text{C } 9)$$

parametrizes the pitch angle  $\lambda$ . Using these simplifications and  $|v_{\perp}|^2/2 = E - |v_{\parallel}|^2/2$ ,

$$\begin{aligned} \langle v_D \rangle &= \left( \int_{-2 \arcsin k}^{2 \arcsin k} \frac{d\vartheta}{\mathbf{b} \cdot \nabla\vartheta} (2\epsilon\lambda B_0)^{-1/2}(k^2 - \sin^2(\vartheta/2))^{-1/2} \right)^{-1} \\ &\quad \int_{-2 \arcsin k}^{2 \arcsin k} \frac{d\vartheta}{\mathbf{b} \cdot \nabla\vartheta} \left[ (2\epsilon\lambda B_0)^{1/2}(k^2 - \sin^2(\vartheta/2))^{1/2} \text{cvdrift} \right. \\ &\quad \left. - 2^{-1/2}(\epsilon\lambda B_0)^{1/2}(k^2 - \sin^2(\vartheta/2))^{1/2} (\nabla|B|)_{\text{drift}} \right. \\ &\quad \left. + 2^{-3/2}(\epsilon\lambda B_0)^{-1/2}(k^2 - \sin^2(\vartheta/2))^{-1/2} (\nabla|B|)_{\text{drift}} \right]. \end{aligned} \quad (\text{C } 10)$$

The following identities simplify (C 10). The incomplete elliptic integrals are converted to complete elliptic integrals using the Reciprocal-Modulus transformation in (C 11) and (C 12) (Olver *et al.* 2024).  $K$  and  $E$  are complete elliptic integrals of the first and second kind, respectively.

$$I_0 = \int_{-2 \arcsin k}^{2 \arcsin k} d\vartheta (k^2 - \sin^2(\vartheta/2))^{-1/2} = 4K(k) \quad (\text{C } 11)$$

$$I_1 = \int_{-2 \arcsin k}^{2 \arcsin k} d\vartheta (k^2 - \sin^2(\vartheta/2))^{1/2} = 4 [E(k) + (k^2 - 1)K(k)] \quad (\text{C } 12)$$

$$I_2 = \int_{-2 \arcsin k}^{2 \arcsin k} d\vartheta (k^2 - \sin^2(\vartheta/2))^{-1/2} \vartheta \sin(\vartheta) = 16 [E(k) + (k^2 - 1)K(k)] \quad (\text{C } 13)$$

$$I_3 = \int_{-2 \arcsin k}^{2 \arcsin k} d\vartheta (k^2 - \sin^2(\vartheta/2))^{1/2} \vartheta \sin(\vartheta) = \frac{32}{9} [E + (k^2 - 1)^2 K] \quad (\text{C } 14)$$

$$I_4 = \int_{-2 \arcsin k}^{2 \arcsin k} d\vartheta (k^2 - \sin^2(\vartheta/2))^{-1/2} \sin^2(\vartheta) = \frac{16}{3} [(2k^2 - 1)E + (1 - k^2)K] \quad (\text{C } 15)$$

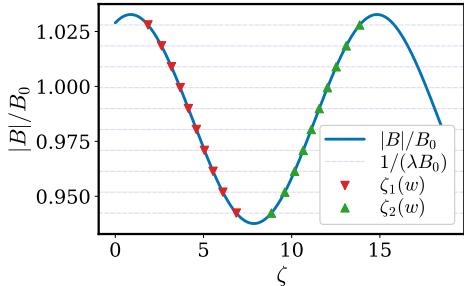

$$\begin{aligned} I_5 &= \int_{-2 \arcsin k}^{2 \arcsin k} d\vartheta (k^2 - \sin^2(\vartheta/2))^{1/2} \sin^2(\vartheta) \\ &= \frac{32}{30} [2(1 - k^2 + k^4)(E - (k^2 - 1)K) - (1 - 3k^2 + 2k^4)k^2 K] \end{aligned} \quad (\text{C } 16)$$

$$I_6 = \int_{-2 \arcsin k}^{2 \arcsin k} d\vartheta (k^2 - \sin^2(\vartheta/2))^{-1/2} \cos(\vartheta) = 8E - 4K \quad (\text{C } 17)$$

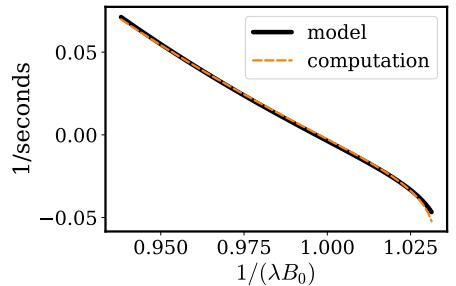

$$I_7 = \int_{-2 \arcsin k}^{2 \arcsin k} d\vartheta (k^2 - \sin^2(\vartheta/2))^{1/2} \cos(\vartheta) = \frac{4}{3} [(2k^2 - 1)E - (k^2 - 1)K] \quad (\text{C } 18)$$

Using these formulae, to lowest order, the bounce-averaged drift is

$$\langle v_D \rangle = \frac{1}{G_0} \left[ f_3 \frac{\alpha_{\text{MHD}}}{B_0^2} I_1 - \frac{f_2}{2} \left( \hat{s} (I_0 + I_1 - I_2 - I_3) + \frac{\alpha_{\text{MHD}}}{B_0^4} (I_4 + I_5) - (I_6 + I_7) \right) \right]. \quad (\text{C } 19)$$

(a) For a pitch marked by a horizontal line,  $|v_\parallel| = 0$  at the points marked by triangles.

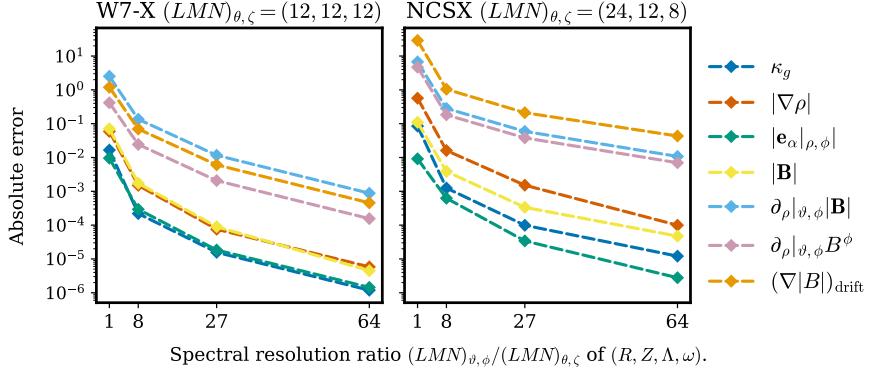

(b) The bounce-averaged binormal drift in the configuration in figure 11a is compared.

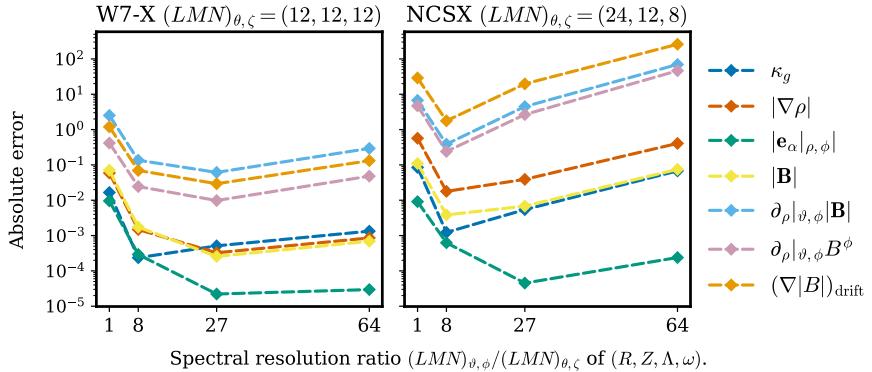

Figure 11: This figure compares our shifted-circle model for the binormal drift to the result computed by our algorithm. The minor difference in figure 11b is because the shifted-circle model is accurate to  $\mathcal{O}(\epsilon^2)$ .

## Appendix D. Issues with changing the spectral basis to straight field line coordinates

In figure 12, we show that parameterizing our basis for  $(R, Z, \Lambda, \omega)$  in straight field line coordinates  $(\vartheta, \phi) = (\theta + \Lambda, \zeta + \omega)$  (Grimm et al. 2012) is inefficient and ill-conditioned.

(a) Equation (3.13) was solved to error  $\leq 10^{-10}$  on the tensor-product of the optimal concentric sampling grid (Ramos-López et al. 2016) in  $(\rho, \vartheta) \in [0, 1] \times [0, 2\pi]$  and a uniform grid in  $\phi \in [0, 2\pi/N_{\text{FP}}]$ .  $(R, Z, \Lambda, \omega)$  were interpolated to a Fourier-Zernike series in  $(\rho, \vartheta, \phi)$  with maximum mode numbers  $(L, M, N)_{\vartheta, \phi}$  on this grid. The interpolation used a  $1.5 \times$  oversampled, in both  $\rho$  and  $\vartheta$ , weighted least-squares fit to improve conditioning for the Zernike series, followed by an FFT in  $\phi$ . (The optimal grid for interpolation to a Zernike series does not coincide with the optimal grid for quadrature to project onto the Zernike basis because the Zernike basis is not a tensor-product basis. Interpolation with a weighted least-squares fit was chosen because the interpolation grid is sparser than the quadrature grid.) Each quantity was then computed on a uniform grid in  $(\rho, \vartheta, \phi)$ . Quadrature required to compute a quantity in the plot was done on an over-sampled grid to account for nonlinearity in the computation from  $(R, Z, \Lambda, \omega)$ . Zernike polynomials were evaluated with stable Jacobi polynomial recurrence relations using the algorithm in Elmacioglu et al. (2025).

(b) This is the same demonstration as figure 12a except equation (3.13) is solved to error  $10^{-7}$ .

Figure 12: This figure shows the error induced by changing the Fourier-Zernike basis for  $(R, Z, \Lambda, \omega)$  from flux coordinates  $(\theta, \zeta)$  to the straight field line coordinates  $(\vartheta, \phi)$ . Fitting at the resolution that obtains the error of  $10^{-4}$  Tesla in  $|B|$  on the NCSX stellarator in figure 12a took 10 minutes with a CPU (Intel Corporation 2019).
